- This contribution presents a statistical analysis about seepage's influence on water hydrodynamics.
- The output of the experiments shows that the artificially induced seepage affects the turbulence dynamics of the open-channel flow. Regardless the significantly small magnitude of the groundwater flow.
- It was observable that seepage modifies the shape of the profiles of analyzed time-averaged parameters of turbulence and in many cases; the open channel flows are not following the laws of isotropic turbulence.
- As a consequence, it is expected that seepage modifies the interaction between the flowing water along the channel and the sediments from the bottom.

Endowed with means that had been reserved for Divine Providence in former times, they change the rain regime, they accelerate the harvest cycle and they change the path of the river, moving it with its white stones and gelid currents to the other extreme of the town, behind the graveyard.

Due to the fact that groundwater flow rates are much smaller than open-channel flow rates; seepage is commonly neglected by river engineers in the analysis of water and environmental issues.

There are cases where the uppermost layer of river beds constitute a porous medium and seepage takes place. Downstream, in the vicinity of these structures, seepage is almost upward.

Conclusions

References

Experimental works concerning seepage's influence on river dynamics were carried out by Ali et al. (2003), Chen and Chiew (2004), Dey and Sarkar (2007), Lu and Chiew (2007), Fontana (2008), Sreenivasulu et al. (2010), 2010a and Herrera Granados (2008c, 2010a) among others.

In the majority of the previously mentioned experimental works, seepage's flow rates were considerably high. But in natural conditions, groundwater flows are much smaller in comparison with stream and river flows. Moreover, results from recent research efforts in this area are often inconclusive and sometimes conflicting (Lu et al., 2008).

The laboratorial research was carried out at the open air laboratory of the Wrocław University of Technology (WUT).

The experimental zone was 8.0 m long, 0.5 m width and 1.0 m high. The first two meters of this experimental zone were used to stabilize the flow in order to address it into subcritical regime to the region where the measurements were recorded.

Using descriptive statistics, time averaged turbulence parameters were calculated such as Reynolds shear stresses in the xy and xz -plane (Directly calculated from the velocity fluctuations). Three open channel flow rates were used during the experiments, depicted in table below.

ID	Flow Rate [dm ³ s ⁻¹]	Flow Averaged Velocity [m s ⁻¹]		Measured k_s [cm s ⁻¹]	Seepage intensity Rate b/a [%]
		a) Open-channel	b) Seepage		
Q_1	11.4	0.440	0.000040	0.00402	0.0091
Q_3	20.0	0.530	0.000039	0.00390	0.0073
Q_5	30.0	0.554	0.000038	0.00379	0.0069

A fine sand soil constituted the porous medium; its d_{50} was around 0.299mm while d_{10} of this sand was estimated around 0.08mm and $\phi=30$ degrees.

Upgrade the experiments that were previously present:

- Using better instrumentation (e.g. laser-based velocimeter, using bed profilers, etc.)
- Increasing the seepage intensities. Carrying out experiment with downward seepage
- Using different soils for the porous medium

- Using different soils for the porous medium

To model the studied phenomenon by a numerical approach is the next step of this research. The output of the numerical model will be compared with the results from the experiments.

There are three proposals to seepage influence on open channel dynamics:

- The zero boundary condition at the channel bed has to be changed considering seepage as a Dirichlet boundary condition (upward inflow = constant).
- To analyze the initiation of sediment motion under seepage conditions.
- Coupling the interaction of seepage and channel hydrodynamics in the same numerical approach. That means that there is a necessity to analyze together laminar or quasi-laminar seepage and turbulent flow in the same model.

The previous analysis demonstrates that the presence of upward seepage influences the velocity fluctuations of the open channel turbulent flow.

Conclusions

Outline

General
Overview

Introduction

Experimental
Works

Further
Research

Conclusions

References

The previous analysis demonstrates that the presence of upward seepage influences the velocity fluctuations of the open channel turbulent flow.

- The presented figures showed that the velocity field is changing when flow through the hyporheic zone exists.
- Additionally, the TKE and the Reynolds stresses are affected by the presence of this groundwater flow.
- Seepage affects the isotropic behavior of the open channel instantaneous velocity field.
- The modification in the behavior of the turbulent stresses can be one of the reasons why seepage is changing sediment transport mechanisms.

A future step of this research is to perform the numerical analysis of this phenomenon:

Conclusions

Final Remarks

Outline

General
Overview

Introduction

Experimental
Works

Further
Research

Conclusions

References

A future step of this research is to perform the numerical analysis of this phenomenon:

- Treating the seepage flow as a new boundary condition in a turbulent model (Easier).
- Integrating the interaction of both processes; which means that there is a necessity to analyze together seepage and open-channel hydrodynamics in the same numerical approach (More difficult).
- Modifying the criteria of predicting sediment incipient motion under seepage conditions (hydrodynamics are neglected).
